ABSTRACT

Objective Over half of patients with IBS have either diarrhoea (IBS-D) or a mixed stool pattern (IBS-M). The relative efficacy of licenced pharmacological therapies is unclear in the absence of head-to-head trials. We conducted a network meta-analysis to resolve this uncertainty.

Design We searched MEDLINE, Embase, Embase Classic, the Cochrane central register of controlled trials, and Clinicaltrials.gov through January 2019 to identify randomised controlled trials (RCTs) assessing the efficacy of licenced pharmacological therapies (alosetron, eluxadoline, ramosetron and rifaximin) in adults with IBS-D or IBS-M. Trials included in the analysis reported a dichotomous assessment of overall response to therapy, and data were pooled using a random effects model. Efficacy and safety of all pharmacological therapies were reported as a pooled relative risk with 95% CIs to summarise the effect of each comparison tested. Treatments were ranked according to their p score.

Results We identified 18 eligible RCTs (seven alosetron, five ramosetron, two rifaximin and four eluxadoline), containing 9844 patients. All were superior to placebo for the treatment of IBS-D or IBS-M at 12 weeks, according to the Food and Drug Administration (FDA)-recommended endpoint for trials in IBS. Alosetron 1 mg twice daily was ranked first for efficacy, based on the FDA-recommended composite endpoint of improvement in both abdominal pain and stool consistency, effect on global symptoms of IBS and effect on stool consistency. Ramosetron 2.5 µg once daily was ranked first for effect on abdominal pain. Total numbers of adverse events were significantly greater with alosetron 1 mg twice daily and ramosetron 2.5 µg once daily, compared with placebo. Rifaximin 550 mg three times daily ranked first for safety. Constipation was significantly more common with all drugs, except rifaximin 550 mg three times daily.

Conclusion In a network meta-analysis of RCTs of pharmacological therapies for IBS-D and IBS-M, we found all drugs to be superior to placebo, but alosetron and ramosetron appeared to be the most effective.

Significance of this study

What is already known on this subject?
► Patients with IBS with diarrhoea (IBS-D) or IBS with mixed stool pattern (IBS-M) have worse quality of life than those with IBS with constipation.
► Up to one-third of these patients use loperamide, but there is little evidence for its efficacy, and many patients report inadequate relief of symptoms.
► Although there are several licenced pharmacological therapies for IBS-D and IBS-M, which are often used as second-line therapy, their relative efficacy is unknown.

What are the new findings?
► We identified 18 randomised controlled trials of pharmacological therapies in IBS-D and IBS-M, containing 9844 patients, with all drugs significantly more effective than placebo.
► Alosetron 1 mg twice daily was ranked the most effective in our primary analysis, using the Food and Drug Administration-recommended composite endpoint for trials in IBS.
► Ramosetron 2.5 µg once daily was ranked the most effective for improvement in abdominal pain, and alosetron 1 mg twice daily was best for improvement in stool consistency.

How might it impact on clinical practice in the foreseeable future?
► Antagonists of 5-hydroxytryptamine-3 (5-HT$_3$) receptors seem to perform best for the symptoms of IBS-D and IBS-M.
► These data suggest either access to existing, licenced 5-HT$_3$ antagonists should be improved, or large trials of older 5-HT$_3$ antagonists, such as ondansetron, are required in patients with IBS-D and IBS-M.

INTRODUCTION

IBS affects 10% of people worldwide and is one of the most common functional bowel disorders.[1] The condition is characterised by abdominal pain, in association with defecation or a change in bowel habit.[2] IBS accounts for a considerable proportion of

referrals to gastroenterology across both secondary and tertiary care settings and, in the USA, is associated with annual direct costs of almost $1 billion, as well as another $50 million in indirect costs.[3] There is a substantial impact on quality of life for patients with active symptoms,[4] which is more pronounced for patients with IBS with diarrhoea (IBS-D) or IBS

with mixed stool pattern (IBS-M)[5] who account for over 50% of people with IBS.[1] These patients often report a fear of incontinence due to loose stools and urgency[6] and can therefore find working and socialising extremely challenging.[7] Although up to one-third of these patients use loperamide,[8] a μ-opioid agonist, as an antidiarrhoeal agent, there is little evidence for its efficacy in IBS,[9] and many patients report inadequate relief of symptoms, other than diarrhoea, with the drug.[8] In addition, although other well-established treatments for IBS, such as antispasmodics or tricyclic antidepressants, may improve abdominal pain,[10 11] many are not licenced for treatment of IBS.

Consequently, over the last 20 years, a number of other pharmacological therapies have been licenced for the treatment of IBS-D and IBS-M. Although they have different mechanisms of action, in clinical practice, all these drugs tend to be used when first-line treatments have failed. Alosetron and ramosetron are both antagonists of the 5-hydroxytryptamine-3 (5-HT$_3$) receptor, an action that may serve to slow gastrointestinal transit, alter rectal compliance[12 13] and reduce visceral sensitivity.[14] Rifaximin is a minimally absorbed broad-spectrum antibiotic that has been tested in IBS-D and IBS-M, on the basis that alterations in gastrointestinal microbiota may, in part, be responsible for symptoms.[15] Finally, eluxadoline is a peripherally acting mixed μ-opioid and κ-opioid receptor agonist, and δ-opioid receptor antagonist, with minimal oral bioavailability, which reduces visceral hypersensitivity and slows gastrointestinal transit.[16]

High-quality placebo-controlled randomised controlled trials (RCTs) have confirmed that all of these licenced drugs are effective treatments for IBS-D and/or IBS-M,[9 17–21] but there have been no head-to-head trials conducted to evaluate relative efficacy. As it is unlikely that any such trials will be performed, we have conducted a network meta-analysis to allow comparisons to be made between all of these drugs, as well as to enable ranking of treatments, in order to inform clinical decisions. This is similar to our recent exercise for drugs used to treat IBS with constipation (IBS-C).[22] The validity of such network meta-analyses can be undermined if there are differences in the design and endpoints used in individual RCTs. However, in this case, the efficacy of all these drugs has been assessed according to endpoints recommended currently for pharmacological therapies in IBS by the Food and Drug Administration (FDA). In addition, as many trials reported the efficacy of each of these drugs, in terms of their effect on individual symptoms, such as abdominal pain or stool consistency, relative efficacy for each drug according to each of these endpoints can also be assessed.

METHODS
Search strategy and study selection
MEDLINE (1947–January 2019), Embase, Embase Classic (1947–January 2019) and the Cochrane central register of controlled trials were searched to identify potential studies. In addition, we searched ClinicalTrials.gov for unpublished trials or supplementary data for potentially eligible studies. In order to identify studies published only in abstract form, conference proceedings (Digestive Diseases Week, American College of Gastroenterology, United European Gastroenterology Week and the Asian Pacific Digestive Week) between 2001 and 2019 were hand-searched. Finally, a recursive search was performed, using the bibliographies of all obtained articles.

Eligible RCTs examined the effect of licenced pharmacological therapies (alosetron, eluxadoline, ramosetron or rifaximin) in adult patients (>18 years) with IBS-D or IBS-M (online supplementary table 1). The first period of cross-over RCTs

were eligible for inclusion if they provided efficacy data prior to cross-over. The definitions of IBS of interest included either a clinician's opinion, or meeting specific diagnostic criteria, for example, the Rome criteria. Only RCTs that examined the efficacy of standard doses of the drugs of interest, and which compared them with each other, or with placebo, were considered eligible. A minimum follow-up duration of 12 weeks was required, in line with FDA recommendations for the design of treatment trials for functional gastrointestinal disorders. All endpoints were extracted at 12 weeks, even for RCTs providing efficacy data at other time points. This was done to ensure as much homogeneity as possible between individual trial results and to avoid overestimating the efficacy of one drug relative to another, as the placebo effect tends to wane with time.[23] Studies had to report a dichotomous assessment of response to therapy. First and senior authors of studies were contacted to provide additional information on individual trials where required.

Two investigators (CJB and ACF) conducted the literature search, independently from each other. Studies on IBS were identified with the terms: *irritable bowel syndrome* and *functional disease(s)*, *colon* (both as medical subject headings and free-text terms) and *IBS, spastic colon, irritable colon* or *functional* adj5 *bowel* (as free-text terms). These were then combined using the set operator AND with studies identified with the following terms: *alosetron, Lotronex, eluxadoline, Viberzi, Truberzi, ramosetron, Irribow, rifaximin* and *Xifaxan* (all as free-text terms).

There were no language restrictions. Two investigators (CJB and ACF) evaluated all abstracts identified by the search for eligibility, again independently from each other. All potentially relevant papers were obtained and evaluated in more detail, using predesigned forms, in order to assess eligibility independently, according to the predefined criteria. Foreign language papers were translated where required. Where multiple articles for a single study were found, wherever possible, we extracted data from the fully published article but used supplementary data concerning any other endpoints of interest from secondary publications or ClinicalTrials.gov, where applicable and relevant. Disagreements between investigators were resolved by discussion.

Outcome assessment
We assessed the efficacy of all drugs, compared with each other or with placebo, in IBS-D and IBS-M in terms of failure to respond to therapy. The included eligible RCTs often used different primary endpoints. However, some of the trials adhered to FDA-recommended endpoints and reported treatment efficacy according to a composite of improvement in both abdominal pain and stool consistency, or we were able to obtain these data from the original investigators. Three of the RCTs of alosetron also applied these criteria retrospectively to a subset of patients in the phase III studies. In addition, because individual trials reported efficacy according to several other secondary endpoints, we were able to assess the efficacy of therapies according to other dichotomous endpoints to define response to treatment. These included: (A) relief of global IBS symptoms (global IBS symptom responder); (B) relief of abdominal pain (abdominal pain responder); and (C) improvement in stool consistency (stool consistency responder). Secondary outcomes included adverse events occurring as a result of therapy (overall numbers of adverse events, regardless of causality, as well as adverse events leading to study withdrawal, and individual adverse events, including constipation, headache, abdominal pain or nausea).

Data extraction

Two investigators (CJB and ACF) extracted all data independently onto a Microsoft Excel spreadsheet (XP professional edition; Microsoft Corp, Redmond, Washington, USA) as dichotomous outcomes (response or no response to therapy). For all included studies, the following data were also extracted for each trial where available: country of origin, number of centres, criteria used to define IBS, subtype of IBS, proportion of female patients and dose and duration of therapy. Data were extracted as intention-to-treat analyses, with dropouts assumed to be treatment failures (ie, no response to therapy), using the total number of patients randomised to each treatment arm as the denominator, wherever trial reporting allowed. If this was not clear from the original article, we performed an analysis on all patients with reported evaluable data.

Quality assessment and risk of bias

This was performed at the study level by two investigators independently (CJB and ACF) using the Cochrane risk of bias tool.[24] Disagreements were resolved by discussion. The method used to generate the randomisation schedule and conceal treatment allocation was recorded, as well as whether blinding was implemented for participants, personnel and outcomes assessment, whether there was evidence of incomplete outcomes data and whether there was evidence of selective reporting of outcomes.

Data synthesis and statistical analysis

We performed a network meta-analysis using the frequentist model, with the statistical package 'netmeta' (version 0.9–0, https://cran.r-project.org/web/packages/netmeta/index.html) in R (V.3.4.2). This was reported according to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension statement for network meta-analyses,[25] in order to explore indirect treatment comparisons of the efficacy and safety of each medication. Network meta-analysis results usually give a more precise estimate, compared with results from standard, pairwise analyses,[26 27] and can also rank treatments to inform clinical decisions.[28]

We examined the symmetry and geometry of the evidence by producing a network plot with node and connection size corresponding to the number of study subjects and number of studies, respectively. We produced comparison-adjusted funnel plots to explore publication bias or other small study effects for all available comparisons versus placebo using Stata V.14. This is a scatterplot of effect size versus precision, measured via the inverse of the SE. Symmetry around the effect estimate line indicates the absence of publication bias or small study effects.[29] We produced a pooled relative risk (RR) with 95% CIs to summarise the effect of each comparison tested, using a random effects model as a conservative estimate. We used an RR of failure to achieve each of the endpoints of interest, where if the RR is less than 1 and the 95% CI does not cross 1, there is a significant benefit of the drug over placebo. As there were no direct comparisons between the active treatment groups, we were unable to perform consistency modelling to check the correlation between direct and indirect evidence.[30]

Global statistical heterogeneity across all comparisons was assessed using the I^2 measure from the 'netmeta' statistical package. The I^2 measure ranges between 0% and 100%. Values of 25%–49%, 50%–74% and ≥75% are typically considered low, moderate and high levels of heterogeneity, respectively.[31] We ranked treatments according to their P-score, which is

a value between 0 and 1. Higher scores indicate a greater probability of the treatment being ranked as best,[32] but the magnitude of the p score should be considered, as well as the treatment rank. As the mean value of the P-score is always 0.5, if individual treatments cluster around this value, they are likely to be of similar efficacy. However, when interpreting the results, it is also important to take the RR and corresponding 95% CIs for each comparison into account, rather than relying on rankings alone.[33] In our primary analysis, we pooled data for the FDA-recommended composite endpoint to define treatment response for all included RCTs that reported these data. We also performed analyses to assess the safety of each medication, including overall numbers of adverse events, and number of adverse events leading to study withdrawal, as well as individual adverse events.

The relative efficacies and safeties of therapies for all outcomes were compared using the 'mvmeta' commands in Stata and a random effects model. Treatments were ranked according to their surface under the cumulative ranking curve value, which is comparable with the P-score used in the frequentist model of our primary analyses.[32]

RESULTS

The search strategy generated 1879 citations, 58 of which appeared to be relevant and were retrieved for further assessment (online supplementary figure 1). Of these, 40 were excluded for various reasons, leaving 18 eligible articles reporting on 18 separate trials, which contained a total of 9844 patients.[17–20 34–47] All trials were fully published, in English, with the exception of one RCT of eluxadoline, identified in abstract form.[47] There were seven RCTs of alosetron (1951 patients alosetron, 1583 placebo),[18 34–39] five trials of ramosetron (1015 patients ramosetron, 913 placebo),[19 40–43] two RCTs of rifaximin (625 patients rifaximin, 635 placebo), reported in one article,[17] and four RCTs of eluxadoline (1967 patients eluxadoline, 1155 placebo), reported in three articles.[20 44 47] A further two articles were also included because together they provided supplementary data,[45 46] reporting efficacy according to FDA-recommended endpoints for alosetron in three phase III RCTs.[18 34 39] These two articles restricted their analyses to female patients who met criteria for severe IBS-D. In addition, the rifaximin trials did not report raw data for many of our analyses of interest in the original article,[17] but we obtained these data from the pharmaceutical company.

Agreement between investigators for trial eligibility was excellent (kappa statistic=0.80). Detailed characteristics of individual RCTs are provided in table 1. Risk of bias for all included trials is reported in online supplementary table 2. Ten trials, reported in eight articles, were at low risk of bias.[17–20 39 42–44] No trials made head-to-head comparisons of one drug versus another, meaning that direct evidence was only available in comparison with placebo. As a result, active medications could only be compared with each other using an indirect evidence meta-analysis.

Efficacy
Failure to achieve the FDA-recommended endpoint to define treatment response

Ten RCTs, reported in seven separate articles, provided dichotomous data for failure to achieve the FDA-recommended composite endpoint at 12 weeks, based on an improvement in abdominal pain and stool consistency.[17 19 20 44–47] Two of

Table 1 Characteristics of randomised controlled trials of pharmacological therapies versus placebo in IBS-D or IBS-M

Study	Country and number of centres	Diagnostic criteria used for IBS and subtypes of IBS recruited	Primary endpoint used to define symptom improvement following therapy by the original investigators	Number of patients (% female)	Number of patients assigned to active drug, dosage, schedule and duration of therapy
Camilleri et al[35]	Multinational, 68 sites.	Rome I criteria, 100% IBS-D or IBS-M.	Adequate relief of pain and discomfort for ≥6 of the 12 weeks of therapy.	152 (44.1).	72 patients received alosetron 1 mg twice daily for 12 weeks.
Camilleri et al[18]	USA, 119 sites.	Rome I criteria, 70.8% IBS-D, 27.8% IBS-M.	Adequate relief of IBS pain and discomfort for ≥2 weeks per month for each of 3 months.	647 (100).	324 patients received alosetron 1 mg twice daily for 12 weeks.
Camilleri et al[34]	USA, 104 sites.	Rome I criteria, 71.2% IBS-D, 27.0% IBS-M.	Adequate relief of IBS pain and discomfort for ≥2 weeks per month for each of 3 months.	626 (100).	309 patients received alosetron 1 mg twice daily for 12 weeks.
Lembo et al[38]	USA, 180 sites.	Rome II criteria, 97.8% IBS-D, 2.2% IBS-M.	Substantial or moderate improvement in global IBS symptoms over the last 4 weeks of therapy.	801 (100).	532 patients received alosetron 1 mg twice daily for 12 weeks.
Chey et al[36]	Multinational, 138 sites.	Rome I criteria, 100% IBS-D.†	Weekly adequate relief of IBS pain and discomfort at week 48 of treatment.‡	569 (100).	279 patients received alosetron 1 mg twice daily for 48 weeks.
Chang et al[37]	USA and Canada, 186 sites.	Rome I criteria, 100% IBS-D.	Adequate relief of IBS pain and discomfort for weeks 5–12 of treatment.	386 (0).	127 patients received alosetron 0.5 mg twice daily and 131 received alosetron 1 mg twice daily for 12 weeks.
Krause et al[39]	USA, number of sites not reported.	Rome II criteria, 100% IBS-D.	Moderate or substantial improvement in global IBS symptoms over the last 4 weeks of therapy.	353 (100).	177 patients received alosetron 1 mg twice daily for 12 weeks.
Matsueda et al[41]	Japan, number of sites not reported.	Rome II criteria, 100% IBS-D.	Complete or considerable relief of global IBS symptoms for ≥2 of the last 4 weeks of therapy.	212 (27.3).	103 patients received ramosetron 5 µg once daily for 12 weeks.
Matsueda et al NCT00189696[40]	Japan, number of sites not reported.	Rome II criteria, 100% IBS-D.	Complete or considerable relief of global IBS symptoms for ≥2 of the last 4 weeks of therapy.	539 (17.9).	270 patients received ramosetron 5 µg once daily for 12 weeks.
Fukudo et al NCT01225237[42]	Japan, 52 sites.	Rome III criteria, 100% IBS-D.	A weekly mean BSFS score of ≥3 to ≤5 and a decrease of ≥1 point in mean BSFS score from baseline for ≥2 of the first 4 weeks of therapy.‡	296 (0).	147 patients received ramosetron 5 µg once daily for 12 weeks.
Fukudo et al NCT01870895[19]	Japan, 70 sites.	Rome III criteria, 100% IBS-D.	Complete or considerable relief of global IBS symptoms for ≥2 of the last 4 weeks of therapy.	576 (100).	292 patients received ramosetron 2.5 µg once daily for 12 weeks.
Fukudo et al NCT01274000[43]	Japan, 61 sites.	Rome III criteria, 100% IBS-D.	Complete or considerable relief of global IBS symptoms for ≥2 of the last 4 weeks of therapy.	305 (100).	104 and 99 patients received ramosetron 2.5 µg or 5 µg once daily, respectively, for 12 weeks.
Pimentel et al (Target 1) NCT00731679[17]	USA and Canada, 179 sites.	Rome II criteria, 100% IBS-D or IBS-M.	Adequate relief of global IBS symptoms for ≥2 of the first 4 weeks after therapy.‡	623 (73.4).	309 patients received rifaximin 550 mg three times daily for 2 weeks.
Pimentel et al (Target 2) NCT00724126[17]	USA and Canada, 179 sites.	Rome II criteria, 100% IBS-D or IBS-M.	Adequate relief of global IBS symptoms for ≥2 of the first 4 weeks after therapy.‡	637 (71.2).	316 patients received rifaximin 550 mg threee times daily for 2 weeks.
Dove et al NCT01130272[44]	USA, 263 sites.	Rome III criteria, 100% IBS-D.	≥30% reduction in worst abdominal pain score and at least two points, and a daily BSFS score of 3 or 4 on ≥66% of daily diary entries at week 4.‡	348 (69.3).	176 patients received eluxadoline 100 mg twice daily for 12 weeks.
Lembo et al (IBS-3001) NCT01553591[20]	USA, Canada and UK, 295 sites.	Rome III criteria, 100% IBS-D.	≥30% reduction in worst abdominal pain score on ≥50% of days and, on the same days, a daily BSFS score of <5 at week 12.	1282 (65.4).	429 and 426 patients received eluxadoline 75 mg or 100 mg twice daily, respectively, for 26 weeks.
Lembo et al (IBS-3002) NCT01553747[20]	USA, Canada and UK, 261 sites.	Rome III criteria, 100% IBS-D.	≥30% reduction in worst abdominal pain score on ≥50% of days and, on the same days, a daily BSFS score of <5 at week 12.	1146 (67.0).	381 and 383 patients received eluxadoline 75 mg or 100 mg twice daily, respectively, for 26 weeks.
Brenner (RELIEF) NCT02959983[47]	USA and Canada, number of sites not reported.	Rome III criteria, 100% IBS-D.	≥40% reduction in worst abdominal pain score on ≥50% of days and a daily BSFS score of <5 at week 12.	346 (69.9).	172 patients received eluxadoline 100 mg twice daily for 12 weeks.

†Also recruited patients with IBS-M, but data were only extractable for those with IBS-D at 12 weeks.
‡Efficacy data were extracted at 12 weeks for the purpose of this analysis.
BSFS, Bristol Stool Form Scale; IBS-D, IBS with diarrhoea; IBS-M, IBS with mixed stool pattern.

the articles, between them, provided sufficient information to enable a post hoc analysis of three of the phase III RCTs of alosetron, which reported efficacy according to FDA-recommended endpoints only in women with severe IBS-D.[45 46]

These 10 trials included a total of 5517 patients, 3156 of whom were randomised to active treatment and 2361 to placebo. The network plot is provided in online supplementary figure 2. When data were pooled, there was no global statistical heterogeneity (I^2=2.3%) and no evidence of publication bias, or other small study effects (online supplementary figure 3). All treatments were significantly more effective than placebo, but alosetron 1 mg twice daily was ranked as the most effective (P-score 0.97) in three RCTs (RR 0.69; 95% CI 0.60 to 0.80) (figure 1). This means that the probability of alosetron being the most effective when all treatments, including placebo, were

compared with each other was 97%. After indirect comparison of active treatments, significant differences were seen with alosetron 1 mg twice daily, compared with all other treatments except ramosetron 2.5 µg once daily (table 2).

Failure to achieve a global IBS symptom response
When dichotomous data were pooled for failure to achieve relief of global symptoms of IBS, there were 13 RCTs, reported in 11 articles, recruiting 7464 patients.[17 19 20 38–44 47] Of these, 4316 were randomised to active treatment and 3148 to placebo. When data were pooled, there was moderate global statistical heterogeneity (I^2=67.4%), which was driven by the trials of alosetron 1 mg twice daily. The comparison adjusted funnel plot for publication bias, or other small study effects, showed no asymmetry
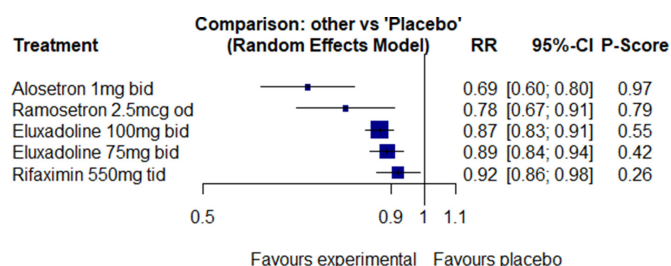

Figure 1 Forest plot of the indirect evidence for failure to achieve the FDA-recommended endpoint to define treatment response. Note: the P-score is the probability of each treatment being ranked as best in the network analysis. A higher score equates to a greater probability of being ranked first. RR, relative risk.

Figure 2 Forest plot of the indirect evidence for failure to achieve a global IBS symptom response. Note: the P-score is the probability of each treatment being ranked as best in the network analysis. A higher score equates to a greater probability of being ranked first. RR, relative risk.

around the zero line (online supplementary figure 4). All treatments were significantly more effective than placebo, with the exception of rifaximin 550 mg three times daily, but alosetron 1 mg twice daily was ranked as the most effective (P-score 0.96) in two RCTs (RR 0.62; 95% CI 0.51 to 0.76) (figure 2). After indirect comparison of active treatments, significant differences were seen with alosetron 1 mg twice daily compared with rifaximin 550 mg three times daily (table 3).

Failure to achieve an abdominal pain response

There were 17 trials recruiting 9043 patients, reported in 15 separate articles,[17–20 34–37 39–44 47] that reported dichotomous data for failure to achieve an abdominal pain response. There were 5026 patients assigned to active therapy and 4017 allocated to placebo. When data were pooled, there was no global statistical heterogeneity ($I^2 = 0\%$) and no evidence of publication bias, or other small study effects (online supplementary figure 5). Ramosetron 2.5 µg once daily, ramosetron 5 µg once daily, alosetron 1 mg twice daily and eluxadoline 100 mg twice daily were all significantly more effective than placebo. Overall, ramosetron 2.5 µg once daily was ranked as the most effective treatment (P-score 0.94) in two RCTs (RR 0.75; 95% CI 0.65 to 0.85) (figure 3). On indirect comparison of active treatments, significant differences were seen with ramosetron 2.5 µg once daily compared with eluxadoline 75 mg twice daily, eluxadoline 100 mg twice daily and rifaximin 550 mg three times daily, as well as for ramosetron 5 µg once daily compared with eluxadoline 75 mg twice daily and rifaximin 550 mg three times daily. Significant differences were also seen for alosetron 1 mg twice daily compared with eluxadoline 75 mg twice daily and rifaximin 550 mg three times daily (online supplementary table 3).
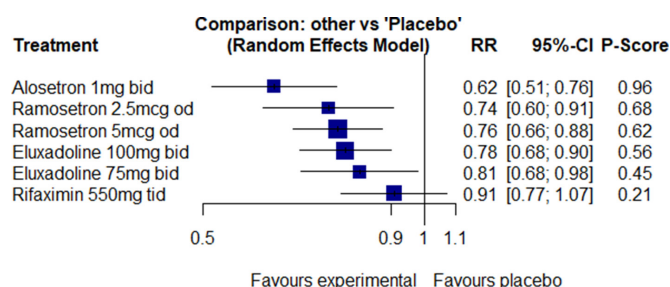

Failure to achieve a stool consistency response

Twelve RCTs reported dichotomous data for failure to achieve a stool consistency response, and these were reported in 10 separate articles and included 6663 patients.[17 19 20 39–44 47] There were 3784 patients assigned to active therapy and 2879 to placebo. When data were pooled, there was no global statistical heterogeneity ($I^2 = 18.4\%$). The comparison adjusted funnel plot for publication bias, or other small study effects, showed no asymmetry around the zero line (online supplementary figure 6). All treatments were significantly more effective than placebo, but alosetron 1 mg twice daily ranked as the most effective treatment (P-score 0.93) although in only one RCT (RR 0.70; 95% CI 0.60 to 0.81) (figure 4). After indirect comparison of active treatments, significant differences were seen with alosetron 1 mg twice daily, compared with eluxadoline 75 mg twice daily and eluxadoline 100 mg twice daily (online supplementary table 4).

Safety

Sixteen trials, recruiting 9134 patients and reported in 14 articles,[17–20 34 37–44 47] provided data for overall adverse events. There was moderate global statistical heterogeneity ($I^2 = 64.2\%$), but no evidence of publication bias, or other small study effects (online supplementary figure 7). Heterogeneity was driven by the trials of alosetron 1 mg twice daily and ramosetron 5 µg once daily. When comparing pooled overall adverse events, alosetron 1 mg twice daily (five RCTs, RR = 1.24; 95% CI 1.09 to 1.41) and ramosetron 2.5 µg once daily (two RCTs, RR = 1.27; 95% CI 1.01 to 1.60) were associated with a significant increase in overall adverse events, compared with placebo (online supplementary figure 8). When ranked using a P-score, rifaximin 550 mg three times daily was the best, and ramosetron 2.5 µg once daily was the worst, in terms of overall adverse events

Table 2 League table for failure to achieve the FDA-recommended endpoint to define treatment response

(P-scores 0.80 and 0.18, respectively). Indirect comparison of active treatments revealed no significant differences between individual drugs and dosages.

Adverse events leading to dropout were provided by 15 trials and were reported in 13 papers.[17 19 20 34 35 38–44 47] Eluxadoline 75 mg twice daily (two RCTs, RR=1.88; 95% CI 1.25 to 2.81), eluxadoline 100 mg twice daily (four RCTs, RR=1.88; 95% CI 1.31 to 2.70) and alosetron 1 mg twice daily (four RCTs, RR=1.97; 95% CI 1.48 to 2.63) were all associated with significantly higher trial dropout rates due to adverse events, compared with placebo. When ranked using a P-score, ramosetron 2.5 µg once daily was the best, and alosetron 1 mg twice daily was the worst, in terms of adverse events leading to dropout (P-scores 0.92 and 0.16, respectively). On indirect comparison of active treatments, significant differences were seen with ramosetron 2.5 µg once daily compared with eluxadoline 100 mg twice daily, eluxadoline 75 mg twice daily and alosetron 1 mg twice daily. Individual adverse events data are provided in the online supplementary materials.

DISCUSSION

It is widely accepted that the licenced pharmacological therapies studied in this systematic review and network meta-analysis are more effective than placebo for the treatment of IBS-D and IBS-M. Using the FDA-recommended composite endpoint, although all drugs were more effective than placebo, alosetron 1 mg twice daily ranked first, according to the available evidence. The probability of alosetron being superior to another competing treatment, according to this endpoint, was 97%, which exceeds

the 90%–95% threshold that the available literature suggests is desirable.[32] Alosetron 1 mg twice daily continued to be ranked first when efficacy was assessed in terms of improvement in global IBS symptoms and stool consistency. Ramosetron 2.5 µg and 5 µg once daily were ranked first and second when effect on abdominal pain was studied. Rifaximin 550 mg three times daily was no better than placebo for global IBS symptoms, and rifaximin 550 mg three times daily, alosetron 0.5 mg twice daily and eluxadoline 75 mg twice daily were no more effective than placebo for abdominal pain. Alosetron 1 mg twice daily and ramosetron 2.5 µg once daily were both associated with a significant increase in overall adverse events, compared with placebo. Constipation was significantly more likely with all drugs, except rifaximin 550 mg three times daily, which ranked first for safety overall. The latter observation may be consistent with the observation that rifaximin may actually accelerate colonic transit[48] and improve symptoms of IBS-C.[49] Finally, more patients reported abdominal pain as an adverse event with eluxadoline and alosetron than with placebo, although whether this is due to the fluctuating natural history of IBS, an associated feature of drug-induced constipation or a specific adverse event associated with both drugs is unclear.

We undertook a contemporaneous and exhaustive literature search. This was conducted independently by two reviewers and included searching conference proceedings, the 'grey' literature and ClinicalTrials.gov. Assessment of eligibility and data extraction was also performed independently and in duplicate. We subsequently contacted the authors of two trials of rifaximin[17] and one trial of eluxadoline,[47] in order to obtain the necessary data for our analyses, as these were not available in the

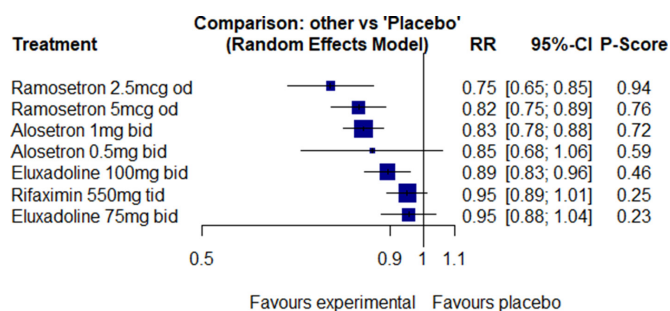

Figure 3 Forest plot of the indirect evidence for failure to achieve an abdominal pain response. Note: the P-score is the probability of each treatment being ranked as best in the network analysis. A higher score equates to a greater probability of being ranked first. RR, relative risk.

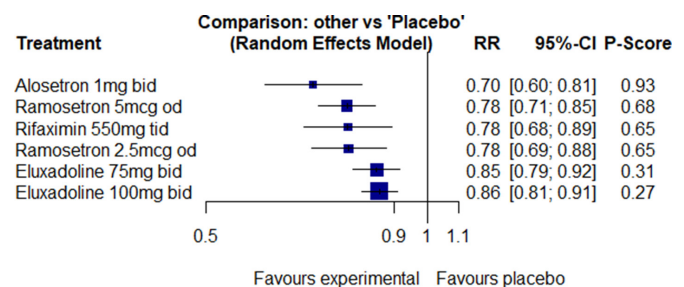

Figure 4 Forest plot of the indirect evidence for failure to achieve a stool consistency response. Note: the P-score is the probability of each treatment being ranked as best in the network analysis. A higher score equates to a greater probability of being ranked first. RR, relative risk.

original papers. This inclusive approach enabled us to analyse data from 18 RCTs of pharmacological therapies for IBS-D and IBS-M, recruiting almost 10 000 patients, with data extracted at 12 weeks for all endpoints. We used an intention-to-treat analysis and pooled data using a random effects model to minimise the risk that the efficacy of the drugs studied would be overestimated. Finally, we extracted and pooled adverse events, where reported, in order to provide summary safety data.

We did not identify any head-to-head studies of one drug versus another, meaning that all our analyses were based on indirect comparisons, which are not protected by randomisation. This could lead to confounding due to underlying differences between individual RCTs,[50] although our use of very similar endpoints to define efficacy after 12 weeks of treatment in all trials should minimise this. However, this means that the relative efficacy and safety of these drugs in the longer term are unknown. In addition, 8 of the 18 trials were at unclear risk of bias,[34–38 40 41 47] which may mean the efficacy of some of the drugs has been overestimated.[51] It is likely that these deficiencies represent omissions of reporting, rather than true design flaws, given the oversight of national regulatory agencies for many of the included trials. There were moderate levels of global statistical heterogeneity in the analysis using an improvement in global IBS symptoms to define treatment response, and for total adverse events, but no heterogeneity in any of our other analyses. It is important to point out that, as in most trials of pharmacological therapies in IBS, adverse events were not reported according to standardised endpoints, unlike efficacy data, which may mean making comparisons between individual treatments is less valid. Finally, there may have been subtle differences in symptom severity among the populations studied in each of these trials, which mean the results are not directly comparable. However, this should have been minimised, as 16 of the trials used similar combinations of a minimum abdominal pain threshold and a minimum stool consistency threshold, during a run-in period, to confirm eligibility prior to study entry. Among the remaining two RCTs: one did not report these data as it was in abstract form[47] and one used a minimum urgency threshold.[38]

Ranking of these pharmacological therapies provides useful information to aid clinical decision making, but it is important to acknowledge that not all of these drugs are available in all countries or, indeed, to all patients with IBS-D or IBS-M. Alosetron was withdrawn in the USA because of adverse events, including ischaemic colitis and severe constipation. It was reintroduced, via a risk evaluation and mitigation strategy for women with severe IBS-D. In the first 9 years after reintroduction, 29 cases of probable ischaemic colitis were reported: an incidence of 1 case per 1000 patient-years.[52] This is similar to the background rate of ischaemic colitis in female patients with IBS, which ranges from 0.40 cases/1000 patient-years to 1.79 cases/1000 patient-years.[53] Whether alosetron is effective in men with IBS-D is unclear, as only one RCT recruited solely men,[37] and participants in the remaining trials were either predominantly, or exclusively, women. However, cilansetron, another 5-HT$_3$ receptor antagonist, appeared to be effective in both men and women with IBS-D.[21] Although ramosetron can be prescribed for men with IBS-D, as well as women, it is only licenced in Japan and some other South, and Southeast, Asian countries, at a dose of 2.5 μg once daily in women and 5 μg once daily in men. However, three of the trials conducted using 5 μg once daily recruited women.[40 41 43] If this dose was either not as effective or less well-tolerated in women, one would have expected this to have diluted efficacy, or led to more adverse events, yet 5 μg once daily was ranked second for its effect on both abdominal pain and stool consistency and was by no means the lowest ranked drug in terms of safety.

Although both alosetron and ramosetron appeared to perform the best in this network meta-analysis, many patients with IBS will be unable to access these drugs. Two recent RCTs of ondansetron, another 5-HT$_3$ receptor antagonist, which is widely available and has a robust safety profile, suggest that this drug is also of benefit in IBS.[54 55] Neither of these trials were eligible for inclusion in our network, as the drug is not licenced for IBS, one trial was a cross-over RCT with a treatment duration of 10 weeks,[54] and the other was a parallel arm trial of only 8 weeks' duration.[55] However, a 12-week trial is in progress in the UK.[56] Another issue is that all of the RCTs of ramosetron were conducted in Japan, and the majority of the trials of alosetron, eluxadoline and rifaximin were conducted in North American populations, so the findings may not be generalisable to individuals with IBS-D or IBS-M in other countries.

Because these studies span the last 20 years of clinical practice, during which time the Rome criteria for IBS have undergone multiple revisions,[2 57–59] there are variations between individual trial populations, in terms of how the diagnosis of IBS was determined. The majority of the alosetron trials and the earlier ramosetron RCTs used the Rome I or II criteria,[57 59] which are arguably less restrictive than the Rome III criteria,[58] used in later trials of ramosetron and all studies of rifaximin and eluxadoline. However, agreement between these criteria for the diagnosis of IBS is good,[60] and such differences are mitigated against, to some extent, by our ability to compare all drugs using the standardised FDA-recommended endpoint for trials in IBS-D. It is important to highlight that, because these endpoints had not been agreed at the time some of the earlier drug trials were conducted, the data for alosetron are based entirely on a post hoc analysis of three trials.[45 46] Around 50% of patients in these trials were absent from the analysis, because they failed to meet the updated FDA-recommended symptom thresholds for inclusion in an IBS treatment trial. This may mean that the efficacy of alosetron has been overestimated for this endpoint, although as only patients with severe IBS-D were included in this analysis, we feel this is unlikely. In addition, the strength of the P-score for alosetron, together with the absence of global statistical heterogeneity, suggests that the treatment ranking we report is likely to be accurate.

All of the drugs considered in this network meta-analysis are likely to be prescribed as second-line therapy, after failure of antidiarrhoeal and anti-spasmodic drugs. It would therefore be important to understand how they perform relative to these first-line therapies, particularly as loperamide is available over the counter in many countries and has evidence of short-term efficacy for reducing diarrhoea.[9] Unfortunately, there are few trials examining this issue. One RCT demonstrated that 12 weeks of alosetron 1 mg twice daily was superior to mebeverine 135 mg three times daily, in terms of adequate relief of abdominal pain, in a mixed population of patients with IBS of all subtypes,[61] but a trial of 4 weeks of ramosetron 5 μg once daily versus mebeverine 135 mg three times daily demonstrated no significant differences.[62]

There have also been no head-to-head trials of these drugs against other second-line therapies, such as tricyclic antidepressants. Additionally, there are no RCTs of tricyclic antidepressants or other pharmacological therapies used off-licence for IBS that have been conducted solely in patients with IBS-D or IBS-M over 12 weeks reporting identical endpoints to the ones used in these trials[9] and that could therefore have been included in this network meta-analysis. Another RCT has compared 24 weeks of alosetron 1 mg twice daily with traditional pharmacotherapy, which in some patients consisted of tricyclic antidepressants, in almost 2000 female

patients with severe IBS-D.[63] In this trial, treatment with alosetron 1 mg twice daily resulted in significantly greater relief of global IBS symptoms. There were also significant reductions in number of visits to see a physician for IBS, use of over the counter medications and days of lost work productivity. However, this beneficial effect was accompanied by non-serious constipation, occurring in one-third of patients, compared with constipation in <1% of those allocated to traditional pharmacotherapy. Initiating alosetron at a dose of 0.5 mg twice daily , and increasing the dose subsequently if there is inadequate clinical improvement, as is currently recommended, may minimise this. Finally, the two large, phase III trials of eluxadoline have reported efficacy of the drug in a subset of patients who had previously failed loperamide,[20] with similar efficacy demonstrated in this post hoc analysis.[8] The most recent RCT of eluxadoline we identified had recruited only patients with IBS-D who reported, subjectively, that they had previously failed loperamide, again with similar results.[47]

Given the lack of head-to-head trials, performing a network meta-analysis could be criticised, because all our conclusions are derived from data based on indirect treatment comparisons. However, as we have discussed previously,[22 64] it is unlikely that pharmaceutical companies will ever conduct such studies or even undertake a trial of one of these drugs against an antidiarrhoeal or tricyclic antidepressant. Network meta-analyses circumvent this problem to some extent, allowing credible ranking systems of the likely efficacy and safety of different treatments to be developed, even in the absence of trials making direct comparisons. The results of our study are therefore still likely to be important for both patients and policy makers, in order to help inform treatment decisions for IBS-D and IBS-M.

In summary, although all drugs were superior to placebo, according to the FDA-recommended composite endpoint for trials in IBS, alosetron 1 mg twice daily ranked first in terms of efficacy in our network meta-analysis. It was also the top ranked treatment when either global relief of symptoms or improvement in stool consistency were used to define treatment response, but ramosetron 2.5 µg once daily was ranked first in terms of improving abdominal pain. With regard to safety, rifaximin 550 mg three times daily was least likely to cause adverse events and was the only drug that did not significantly increase the risk of constipation. However, it demonstrated relatively poor efficacy across many of the treatment endpoints we studied. Eluxadoline 100 mg twice daily, meanwhile, was significantly better than placebo across all endpoints, but its overall performance was modest. This information will hopefully assist clinicians in choosing a second-line treatment for IBS-D, and to a lesser extent IBS-M, based on the patient's most troublesome symptom, considering both efficacy and safety. Alosetron and ramosetron remain unavailable in many countries. Given the chronic and frequently debilitating nature of IBS, this lack of availability may need to be reconsidered, in order to widen access to potentially effective second-line treatments for those patients with IBS-D or IBS-M when conventional first-line therapies fail.
